# Decision trees (DT)

Dependent variable: PLAY

#### The classifier:

 $f_T(x)$ : majority class in the leaf in the tree T containing x

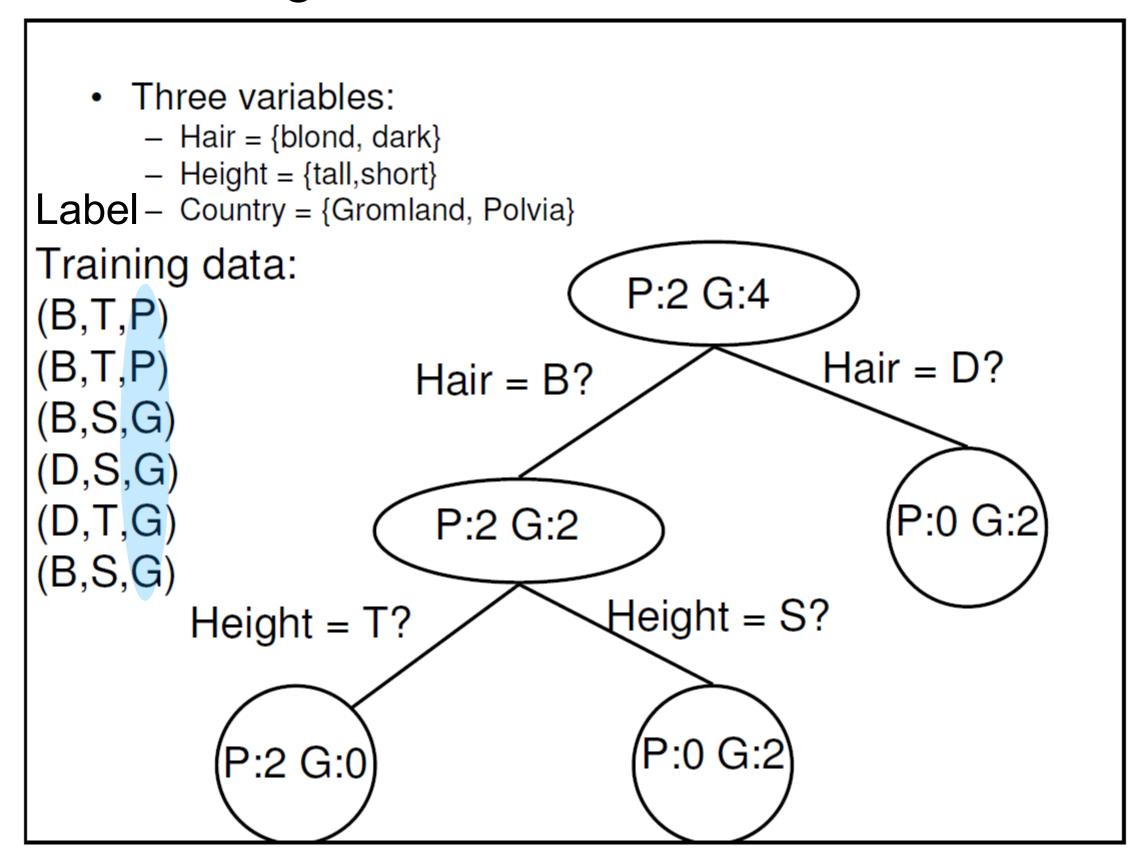

**Model parameters:** The tree structure and size

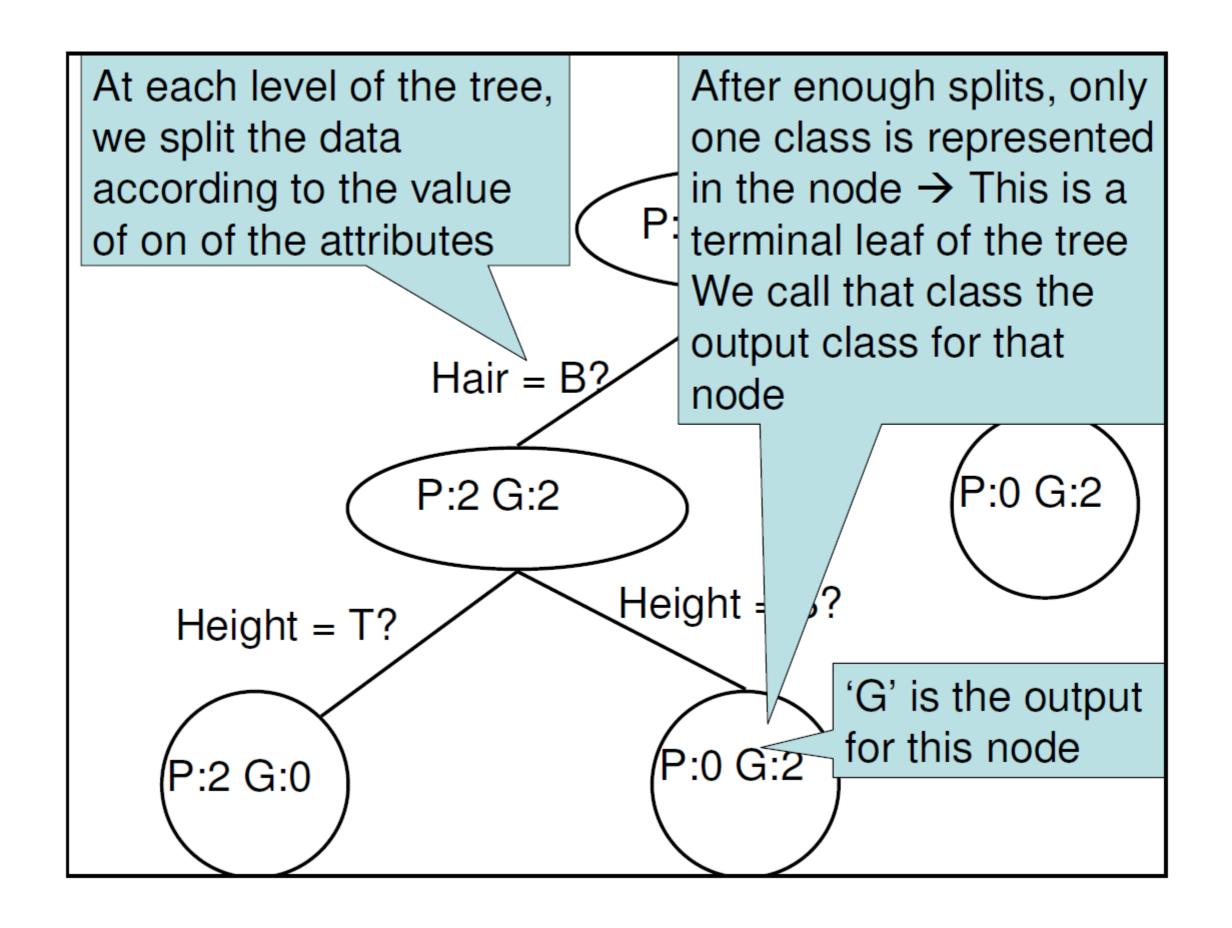

#### Decision trees

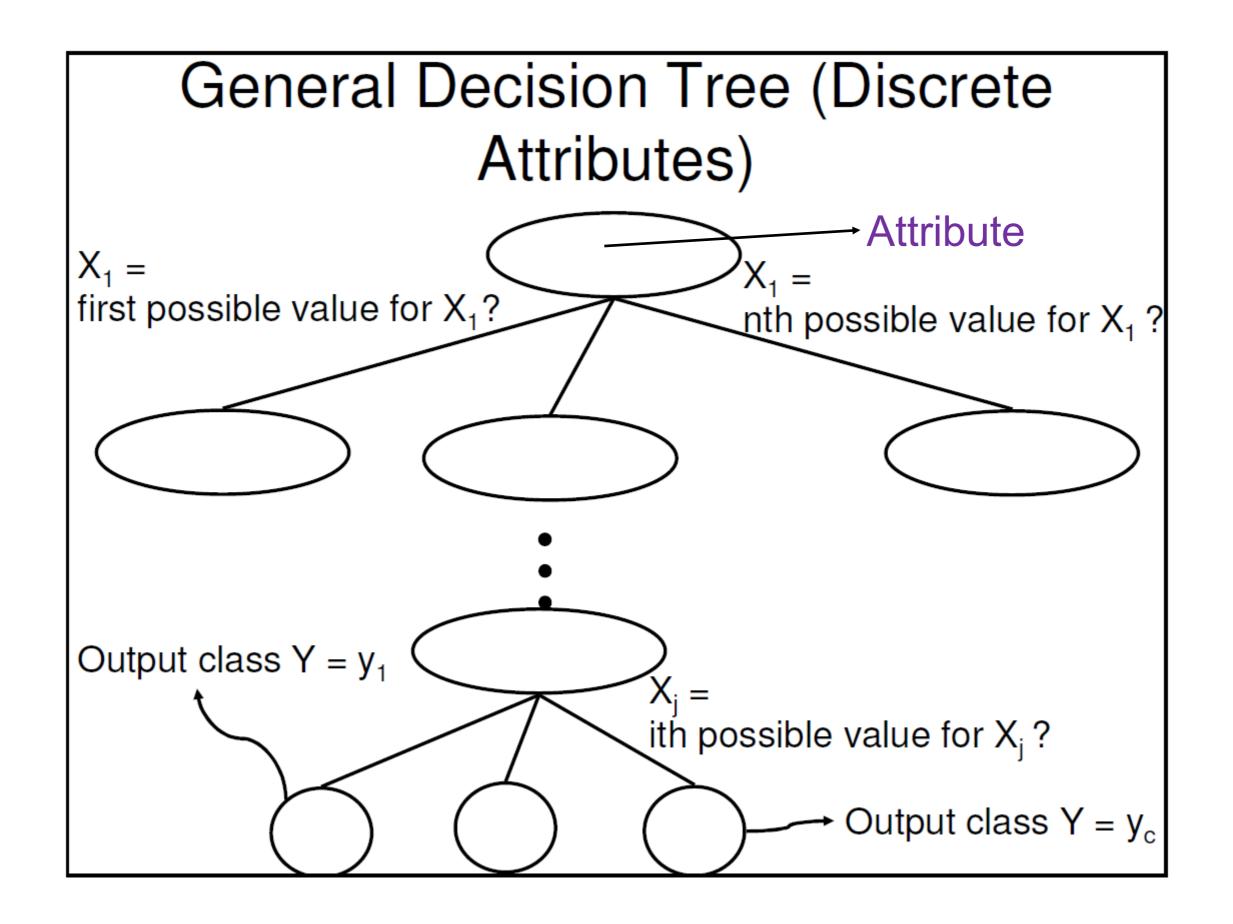

#### Pieces:

- 1. Find the best attribute to split on
- 2. Find the best split on the chosen attribute
- 3. Decide on when to stop splitting

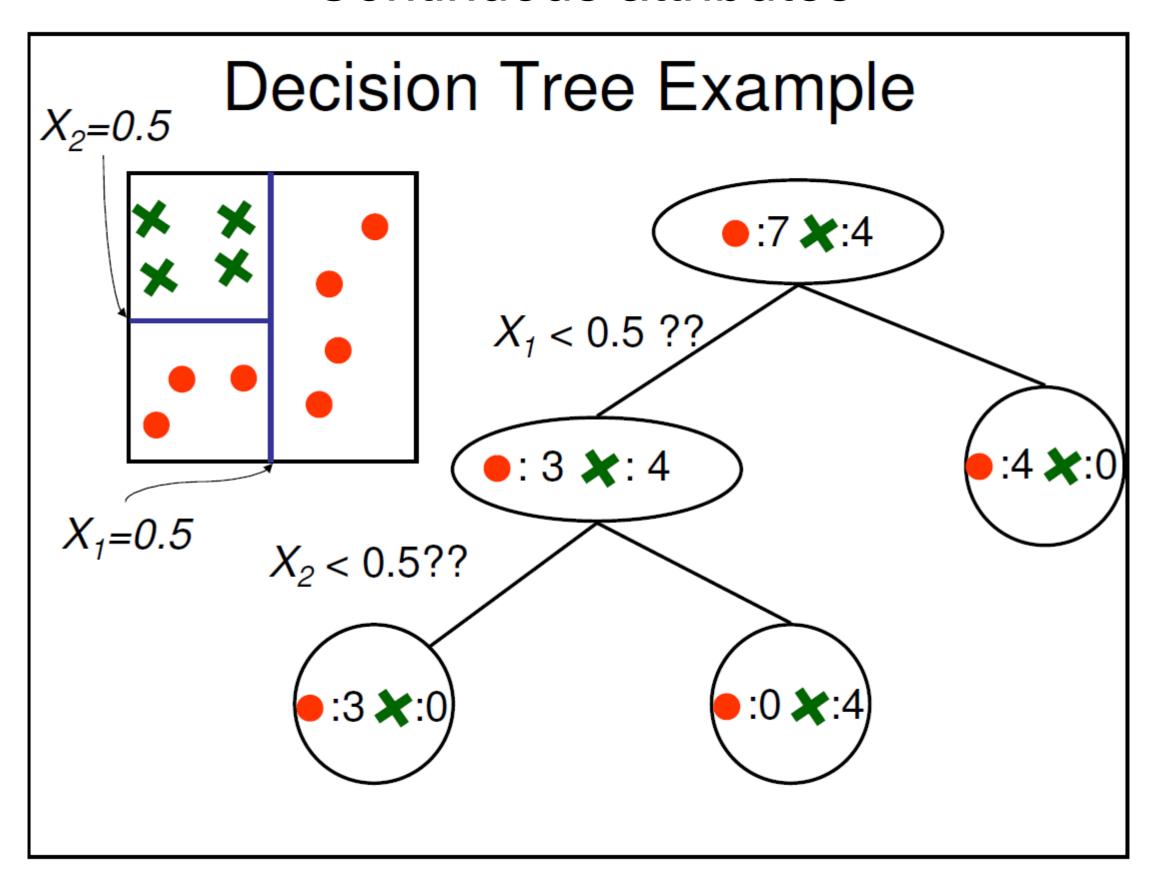

## Categorical or Discrete attributes

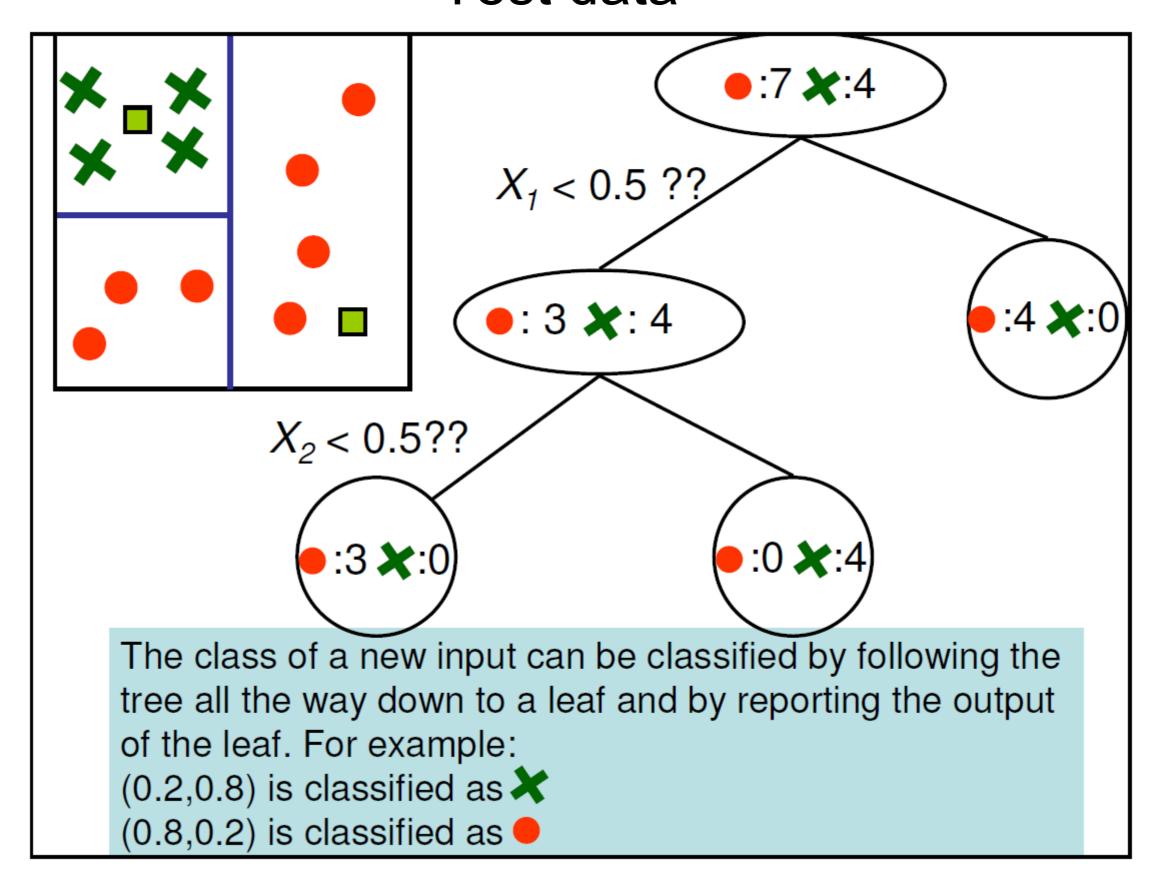

#### Continuous attributes

#### Test data

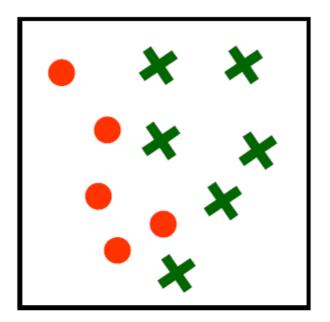

# General Decision Tree (Continuous Attributes) $X_1 < t_1$ ? Output class $Y = y_1$ $X_i < t_i$ ? Output class Y = y<sub>c</sub>

## **Basic Questions**

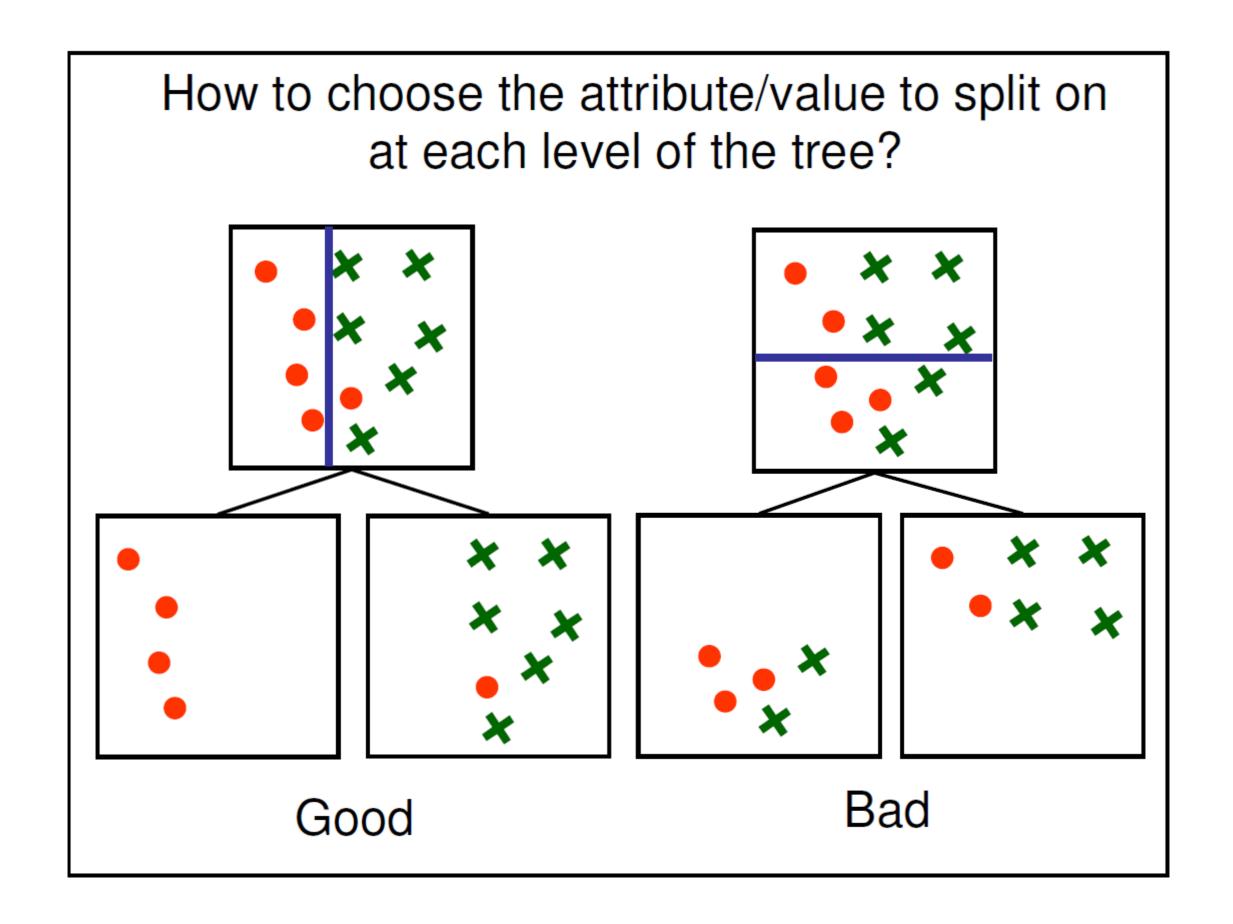

- How to choose the attribute/value to split on at each level of the tree?
- When to stop splitting? When should a node be declared a leaf?
- If a leaf node is impure, how should the class label be assigned?
- If the tree is too large, how can it be pruned?

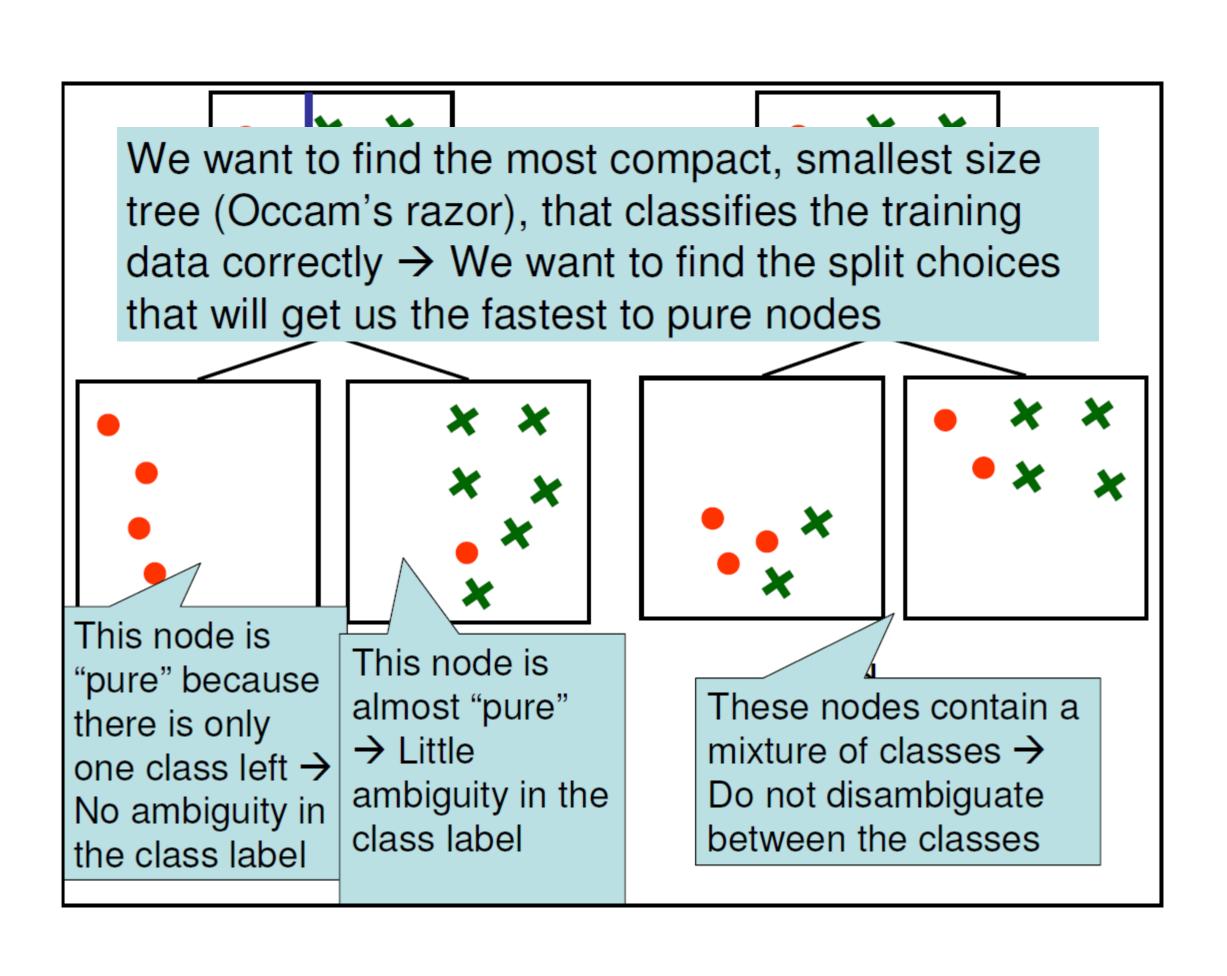

How to choose the attribute/value to split on at each level of the tree?

- Two classes (red circles/green crosses)
- Two attributes: X<sub>1</sub> and X<sub>2</sub>
- 11 points in training data
- Idea 

  Construct a decision tree such that the leaf nodes predict correctly the class for all the training examples

#### **Information Content**

#### Coin flip

$C_{1H}$	0
$C_{1T}$	6

$$P(C_{1H}) = 0/6 = 0$$

$$P(C_{1T}) = 6/6 = 1$$

$C_{2H}$	1
$C_{2T}$	5

$$P(C_{2H}) = 1/6$$

$$P(C_{2T}) = 5/6$$

$C_{3H}$	2
$C_{3T}$	4

$$P(C_{3H}) = 2/6$$

$$P(C_{3T}) = 4/6$$

Which coin will give us the purest information? Entropy ~ Uncertainty

ower uncertainty, higher information gain

$$H(X) = -\sum_{i=1}^{N} P(x=i) \log_2 P(x=i)$$

Entropy = 
$$-0 \log 0 - 1 \log 1 = -0 - 0 = 0$$

Entropy = 
$$-(1/6) \log_2 (1/6) - (5/6) \log_2 (5/6) = 0.65$$

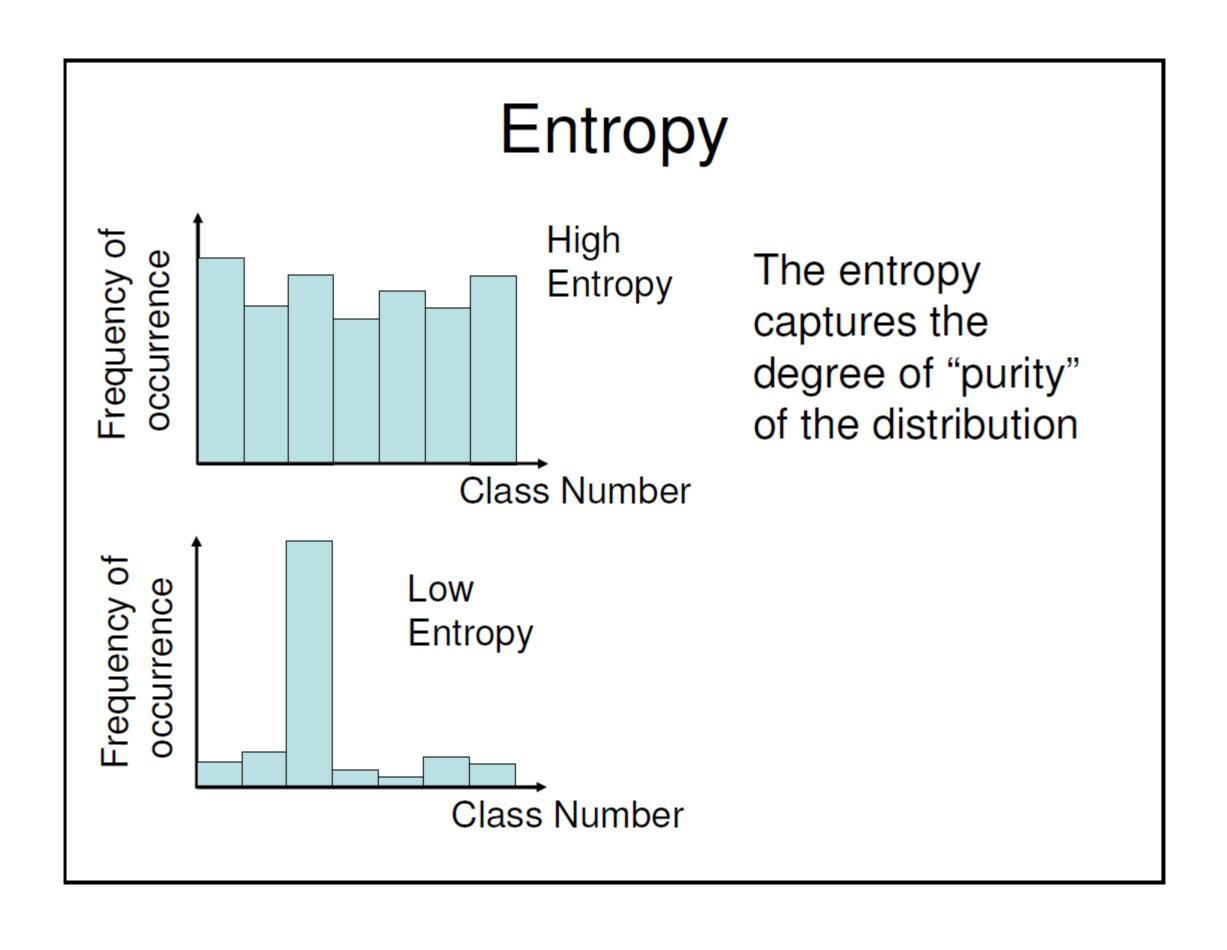

Entropy = 
$$-(2/6) \log_2(2/6) - (4/6) \log_2(4/6) = 0.92$$

# Entropy

 In general, the average number of bits necessary to encode n values is the entropy:

$$\boldsymbol{H} = -\sum_{i=1}^{n} \boldsymbol{P}_{i} \log_{2} \boldsymbol{P}_{i}$$

- P<sub>i</sub> = probability of occurrence of value i
  - High entropy -> All the classes are (nearly) equally likely
  - Low entropy -> A few classes are likely; most of the classes are rarely observed

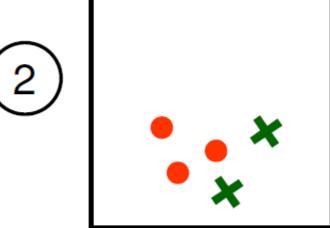

# Example Entropy Calculation

$$N_A = 1$$
  
 $N_B = 6$ 

$$p_A = N_A/(N_A + N_B) = 1/7$$
  
 $p_B = N_B/(N_A + N_B) = 6/7$ 

$$N_A = 3$$
  
 $N_B = 2$ 

$$p_A = N_A/(N_A + N_B) = 3/5$$
  
 $p_B = N_B/(N_A + N_B) = 2/5$ 

$$H_1 = -p_A \log_2 p_A - p_B \log_2 p_B$$
  $H_2 = -p_A \log_2 p_A - p_B \log_2 p_B$   
= 0.59 = 0.97

$$H_1 < H_2 => (2)$$
 less pure than (1)

# Conditional Entropy

Entropy before splitting: H

After splitting, a fraction  $P_L$  of the data goes to the left node, which has entropy  $H_L$ 

After splitting, a fraction  $P_R$  of the data goes to the left node, which has entropy  $H_R$ 

The average entropy after splitting is:

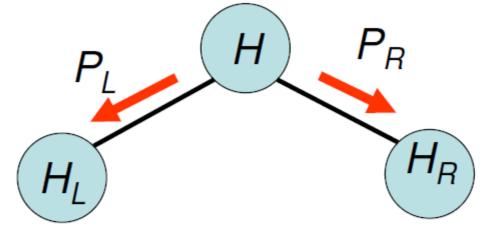

Entropy of left node

$$H_L \times P_L + H_R \times P_R$$

"Conditional Entropy"

Probability that a random input is directed to the left node

## Information Gain

We want nodes as pure as possible

- → We want to reduce the entropy as much as possible
- → We want to maximize the difference between the entropy of the parent node and the expected entropy of

the children

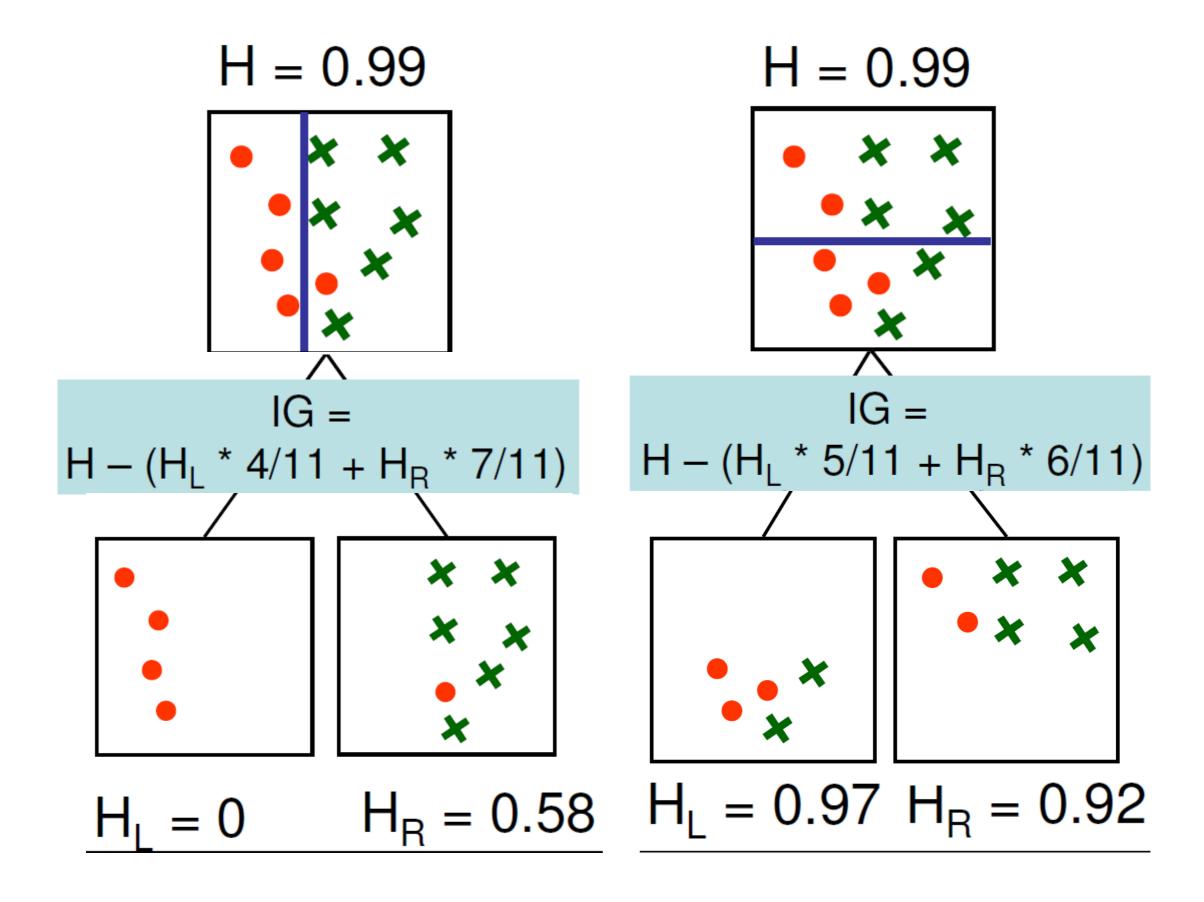

Information Gain (IG) = Amount by which the ambiguity is decreased by splitting the node

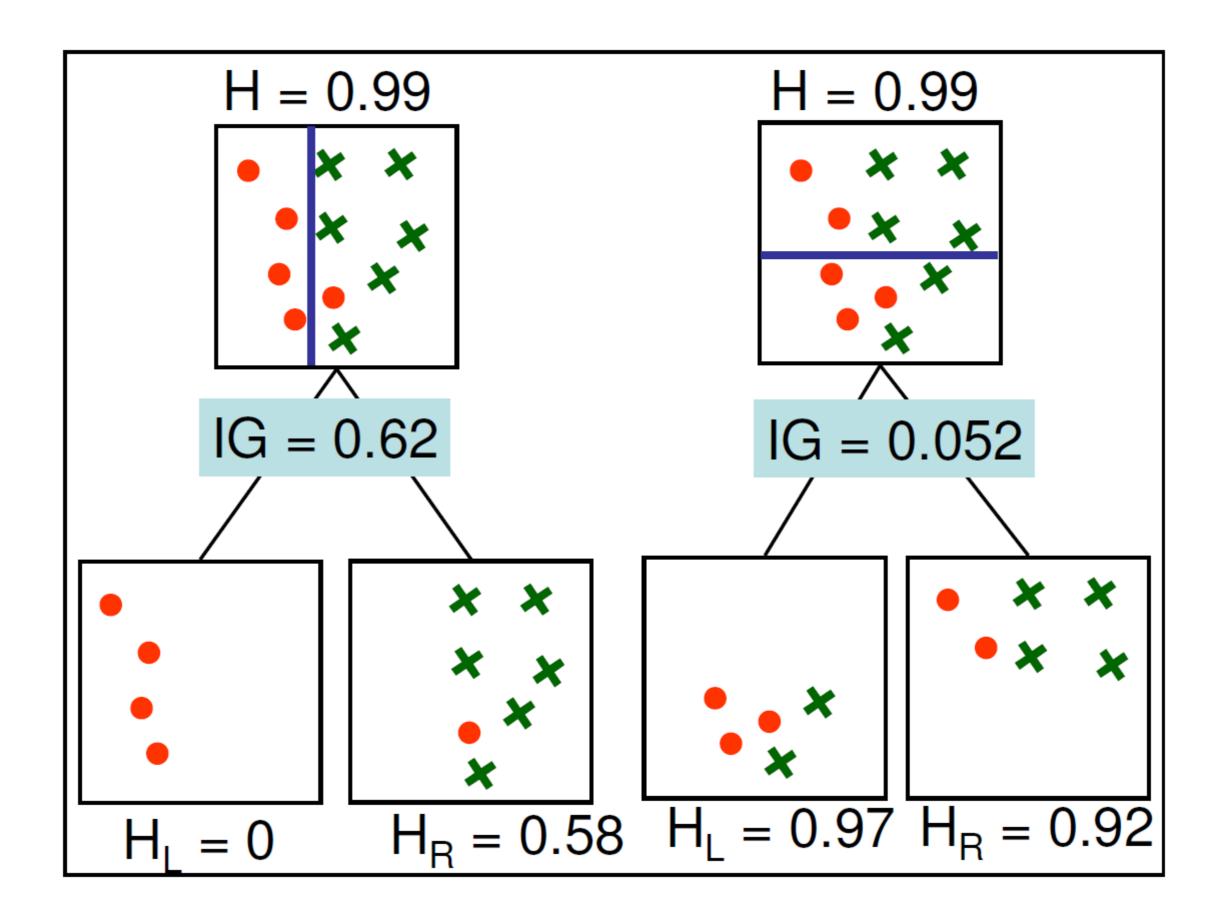

Maximize:

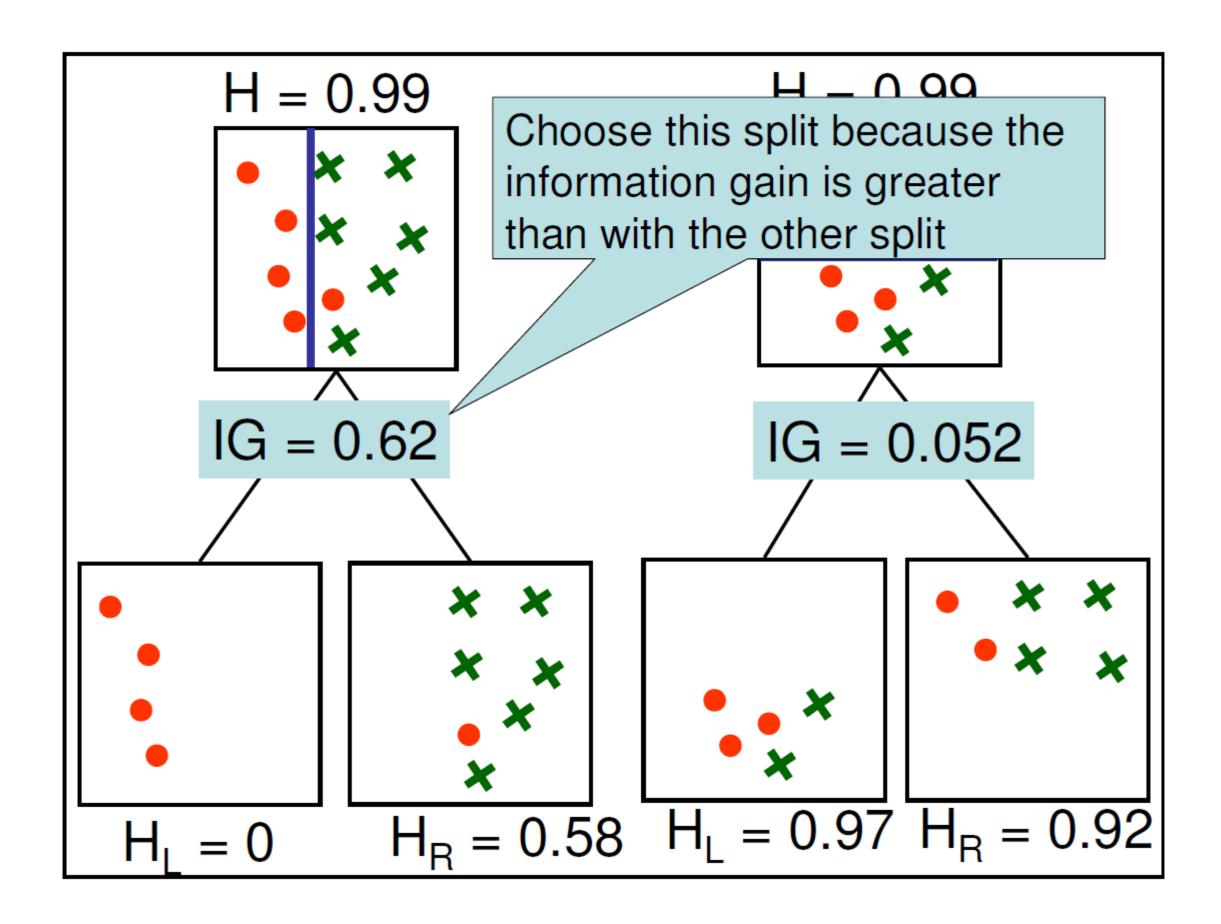

$$IG = H - (H_L \times P_L + H_R \times P_R)$$

#### **Notations**

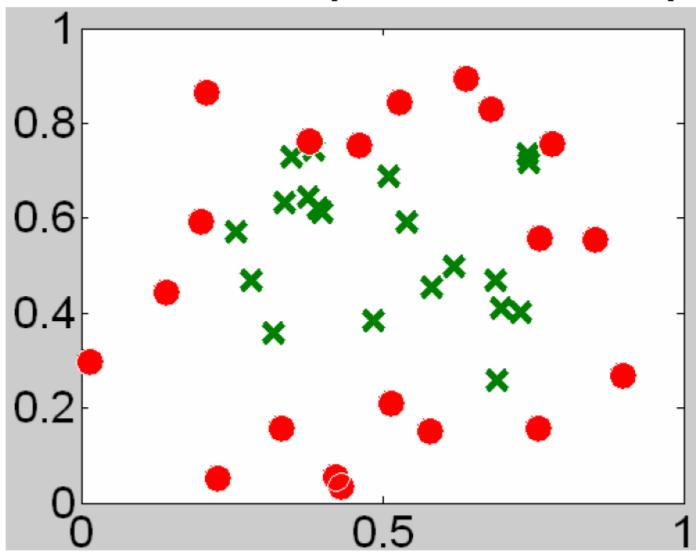

- Entropy: H(Y) = Entropy of the distribution of classes at a node
- Conditional Entropy:
  - Discrete:  $H(Y|X_j)$  = Entropy after splitting with respect to variable j
  - Continuous:  $H(Y|X_j,t)$  = Entropy after splitting with respect to variable j with threshold t
- Information gain:
  - Discrete:  $IG(Y|X_j) = H(Y) H(Y|X_j) = Entropy$  after splitting with respect to variable j
  - Continuous:  $IG(Y|X_j,t) = H(Y) H(Y|X_j,t) =$ Entropy after splitting with respect to variable j with threshold t

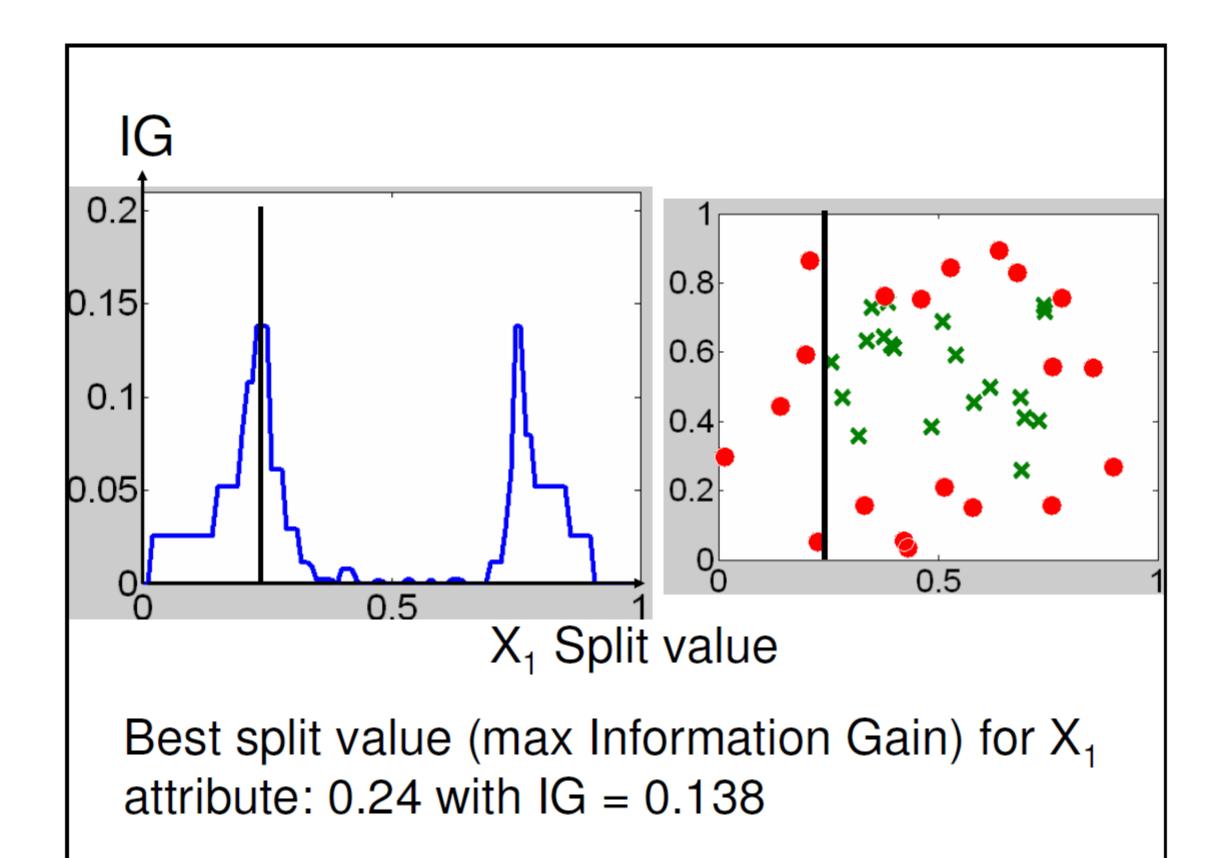

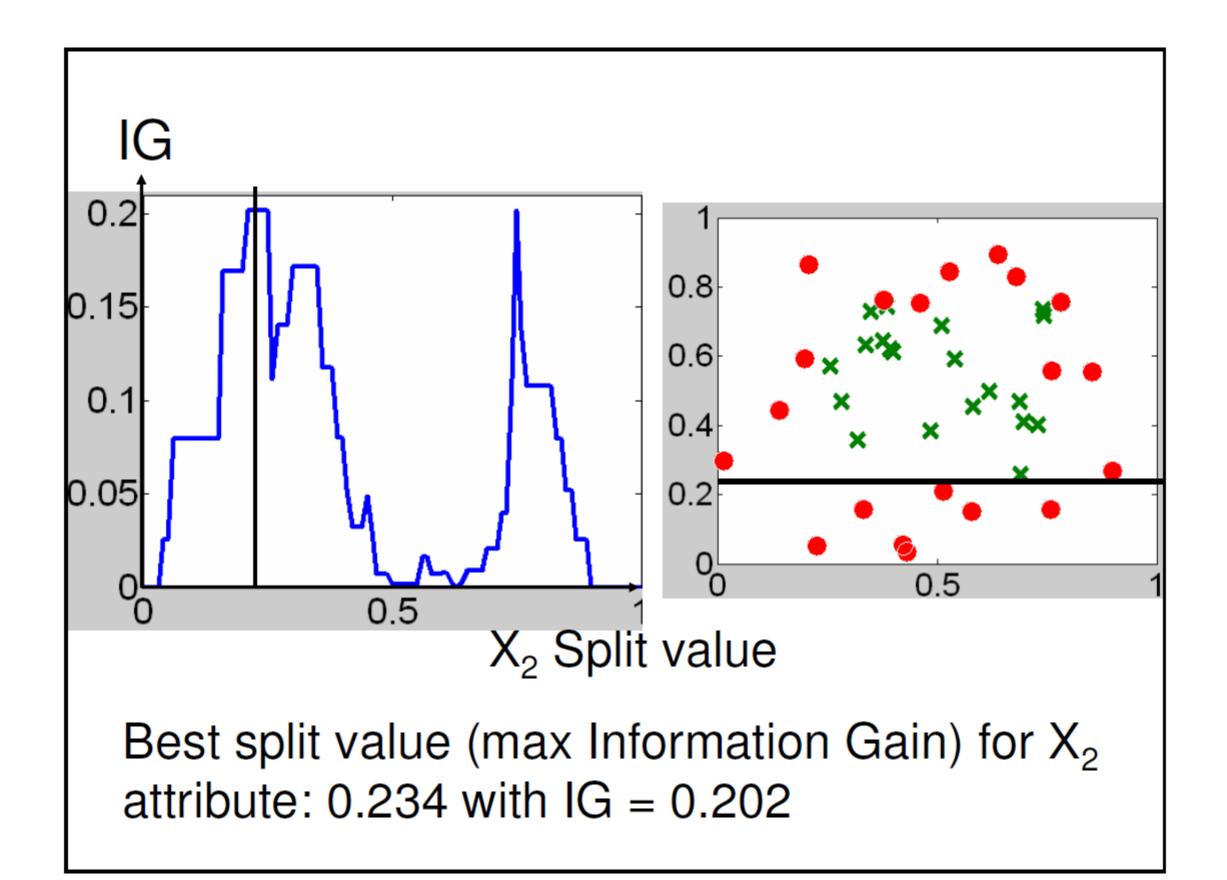

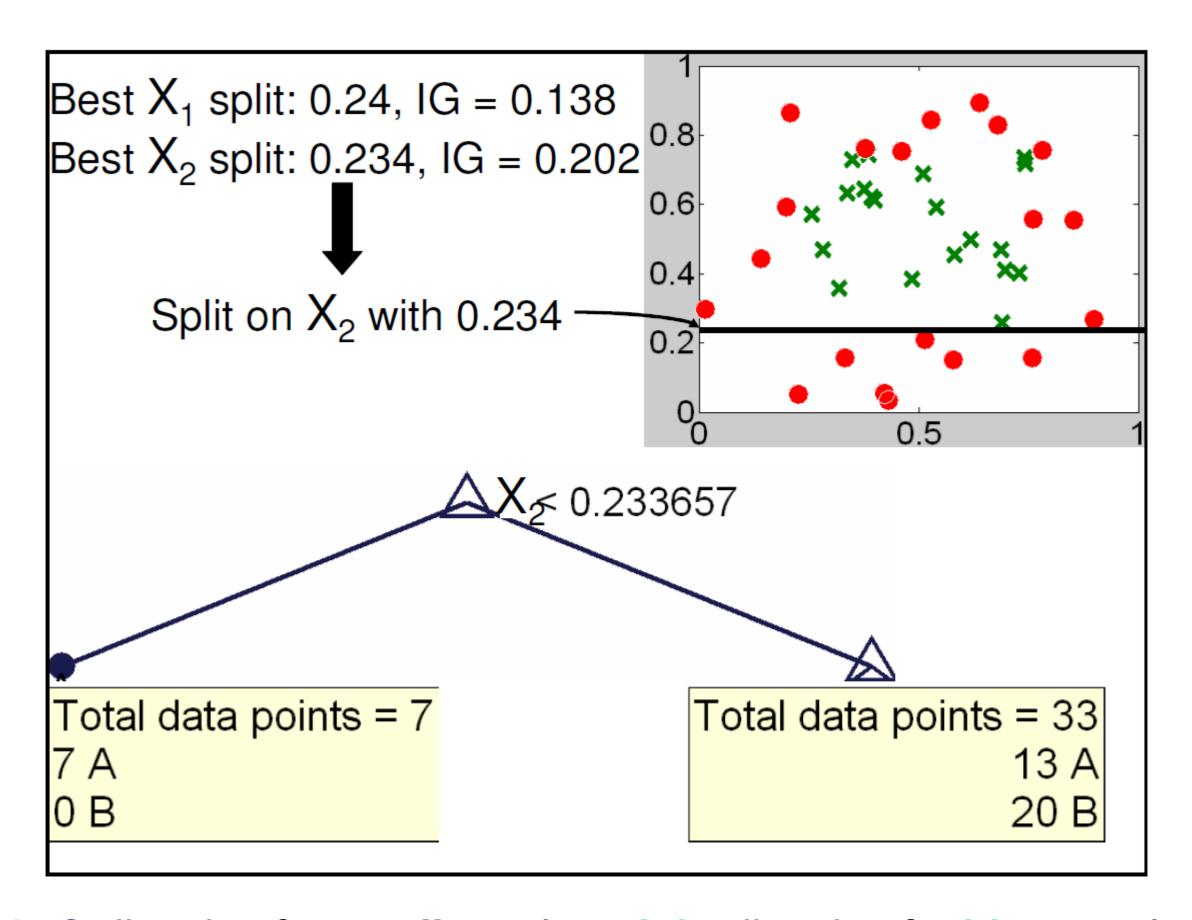

# More Complete Example

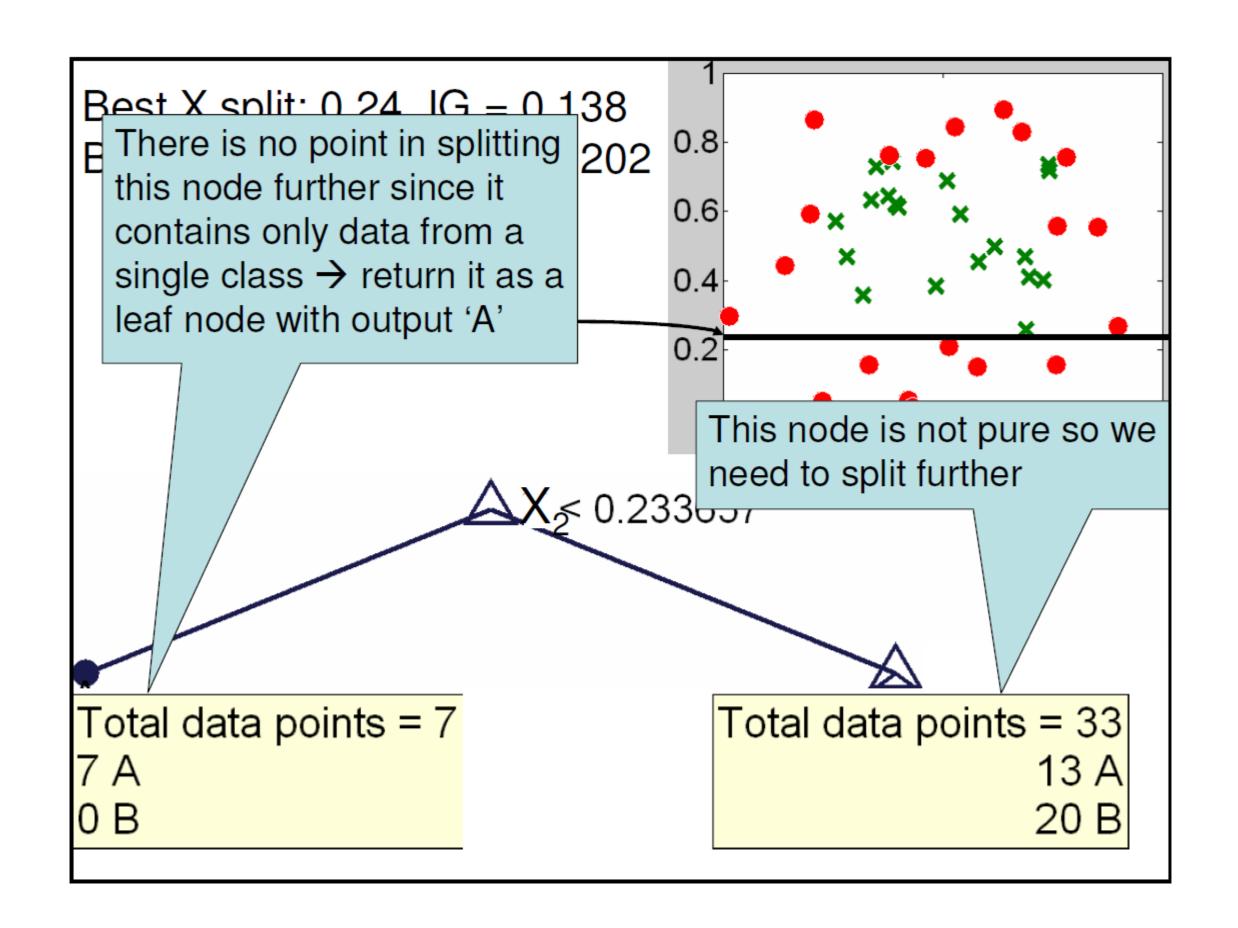

- = 20 training examples from class A
- X = 20 training examples from class B Attributes = X₁ and X₂ coordinates

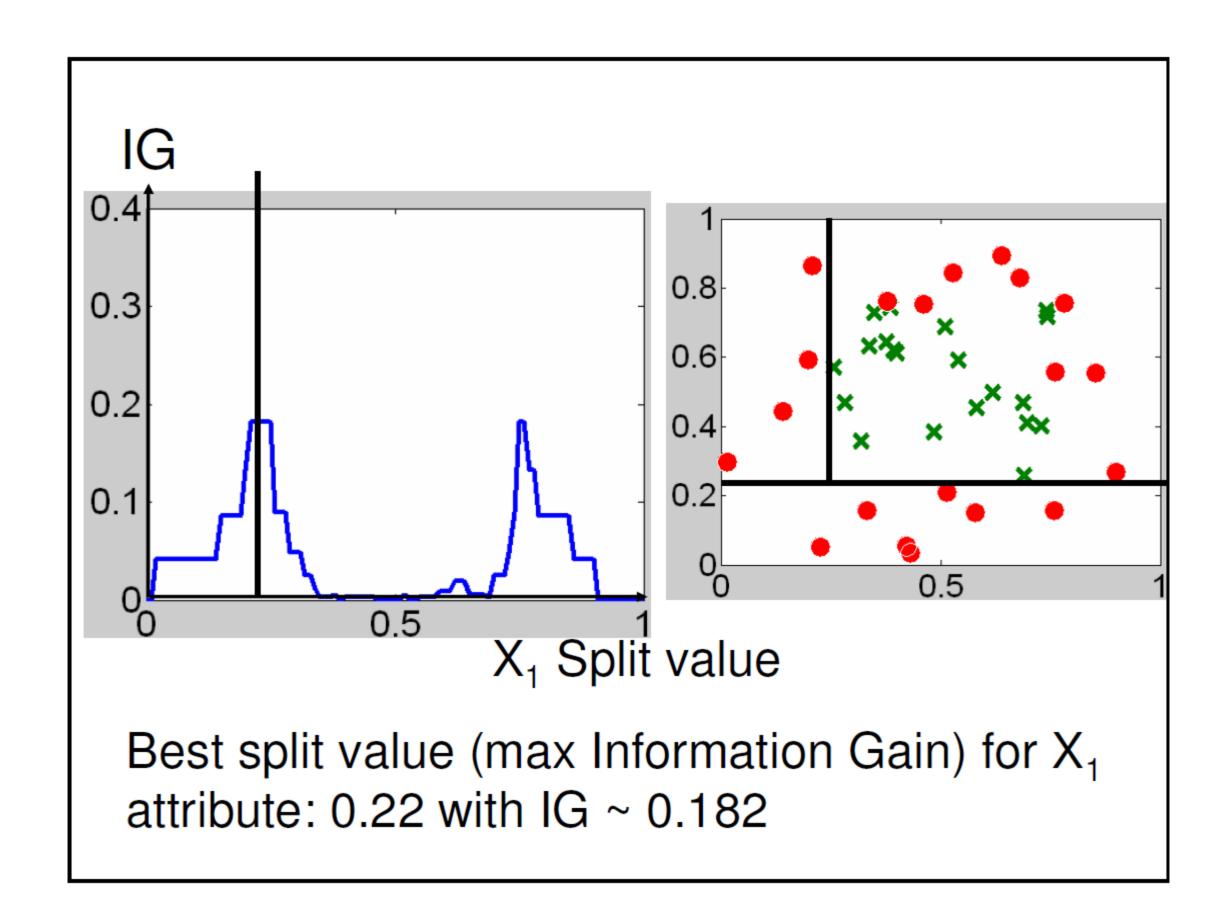

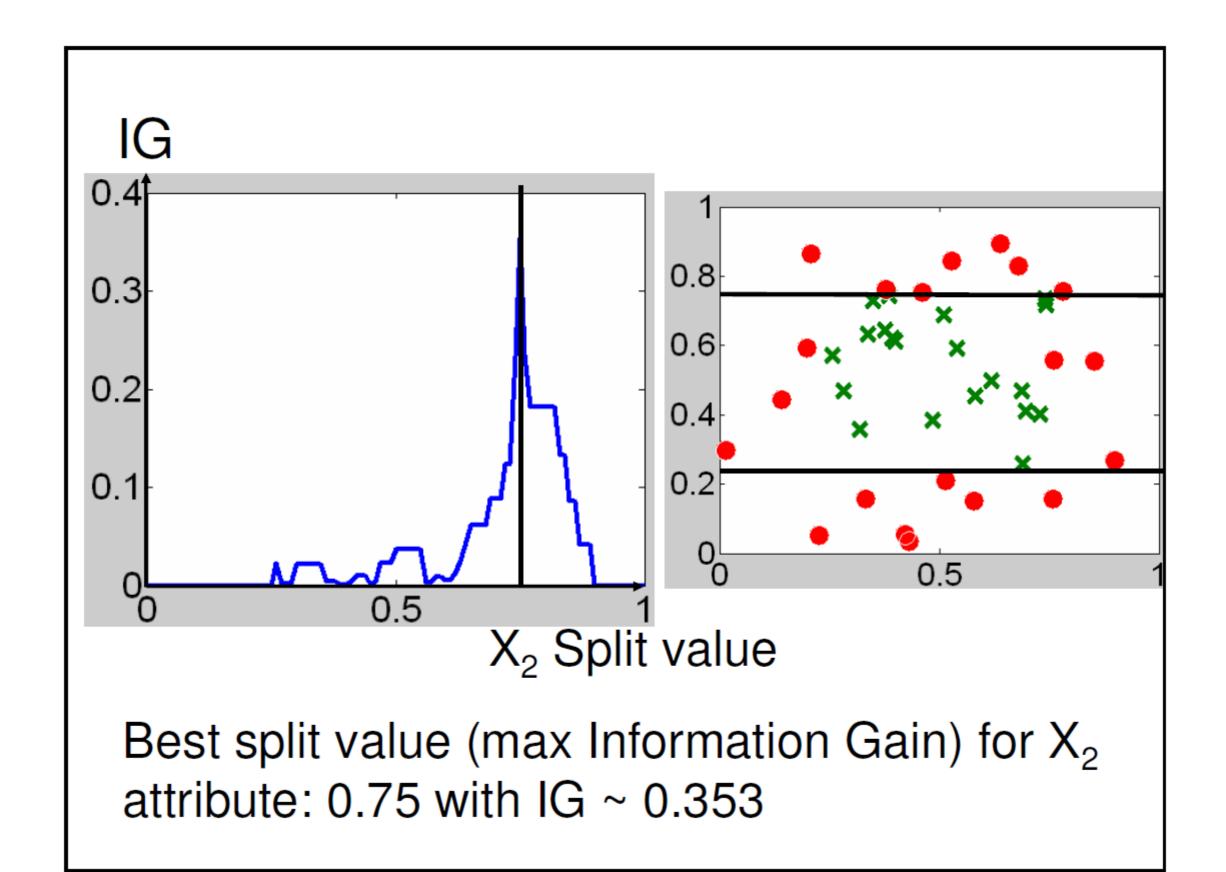

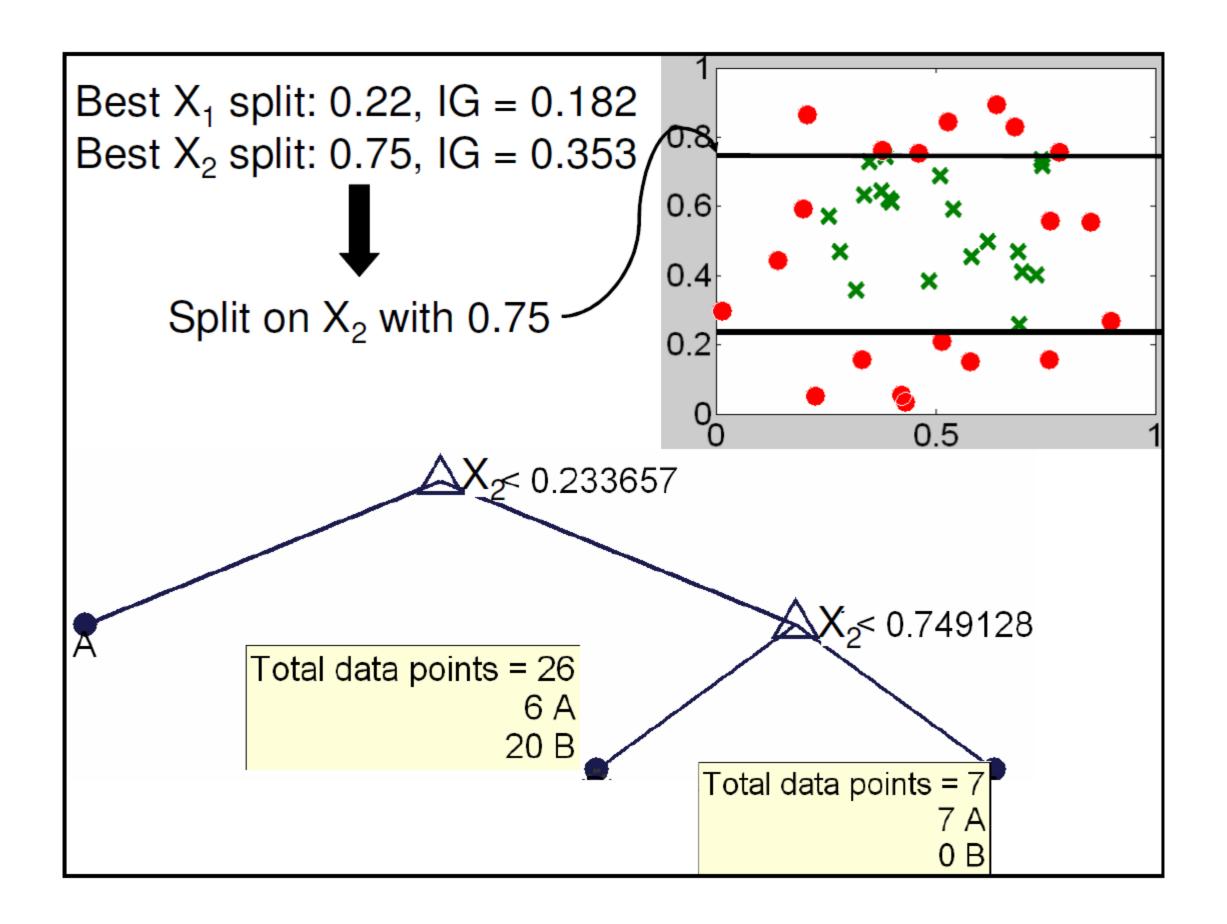

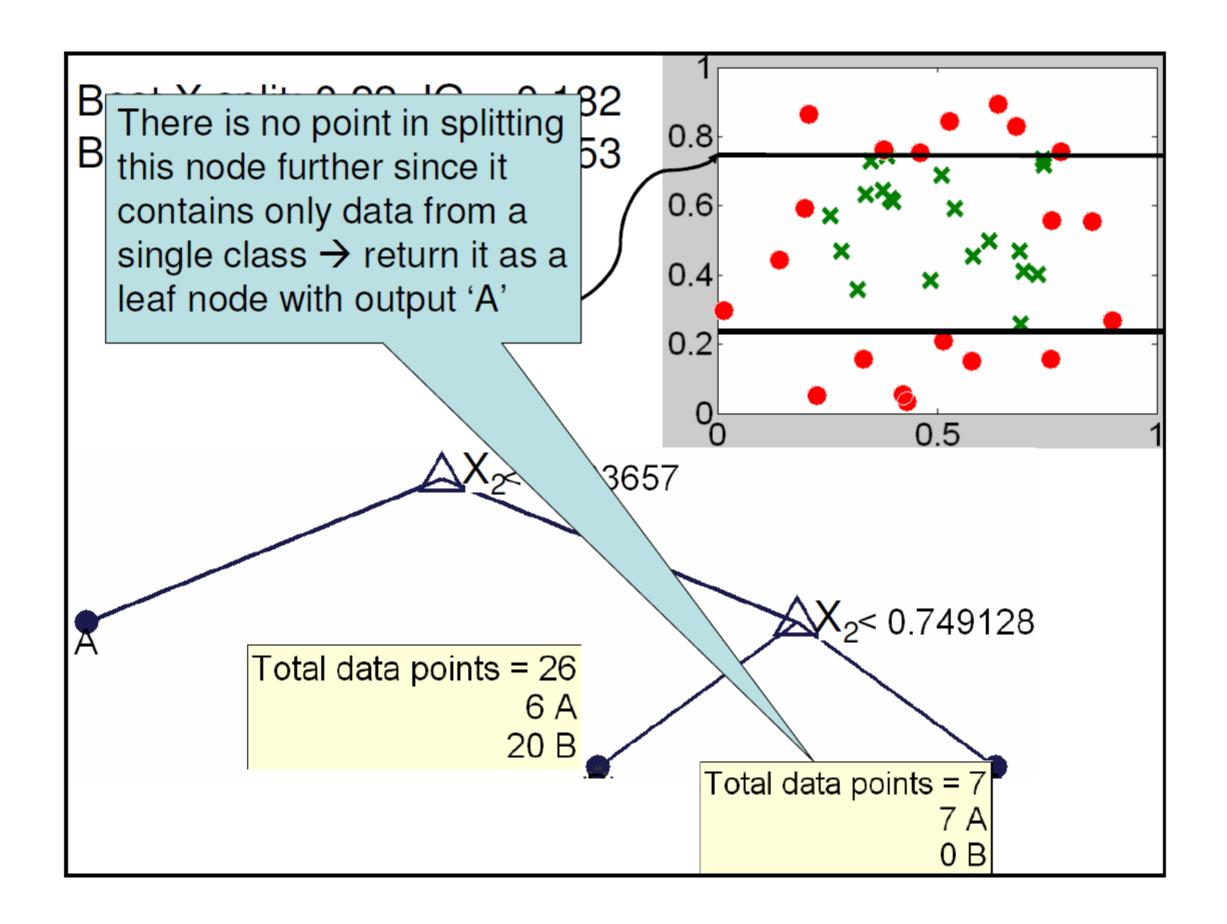

Left direction for smaller value, right direction for bigger value

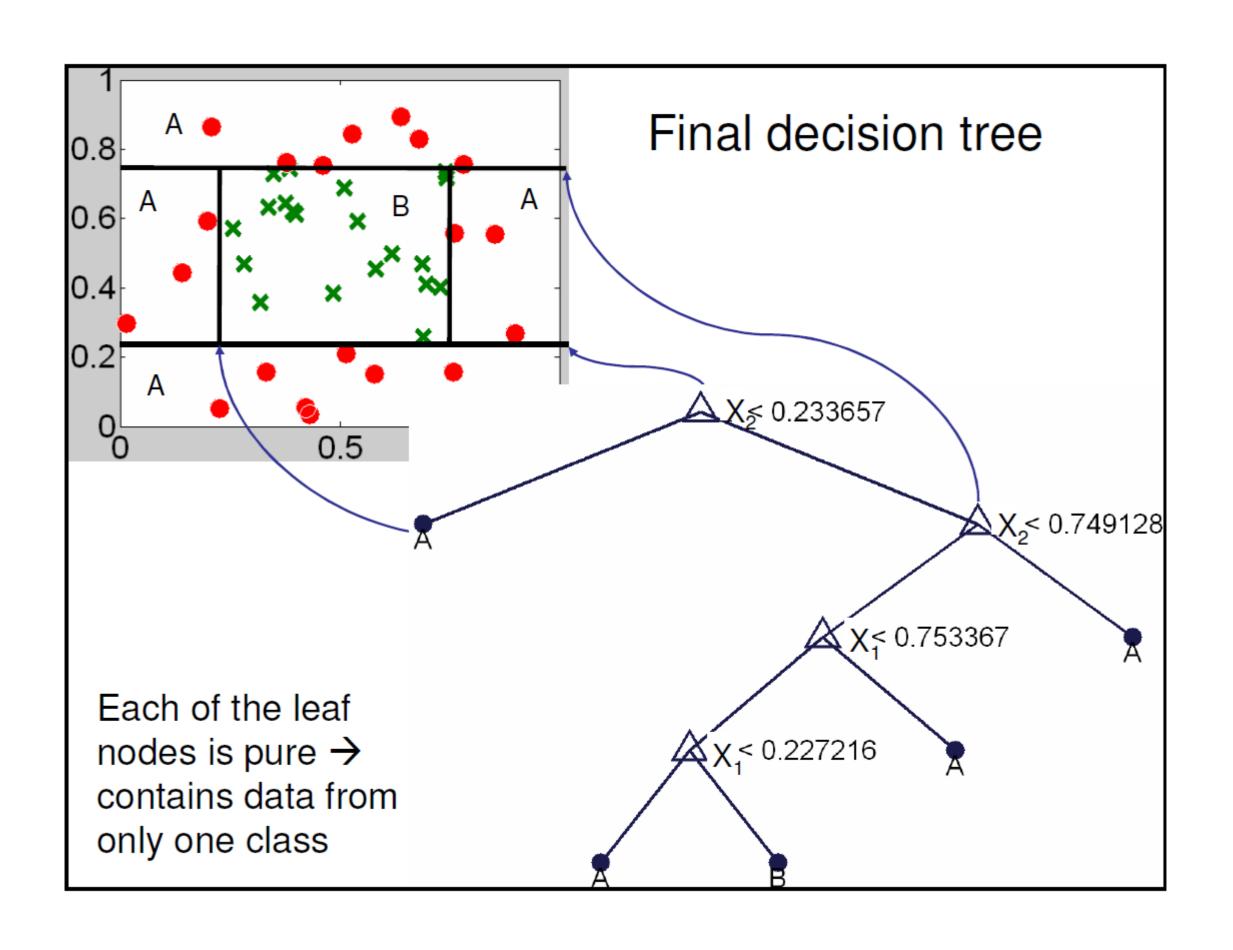

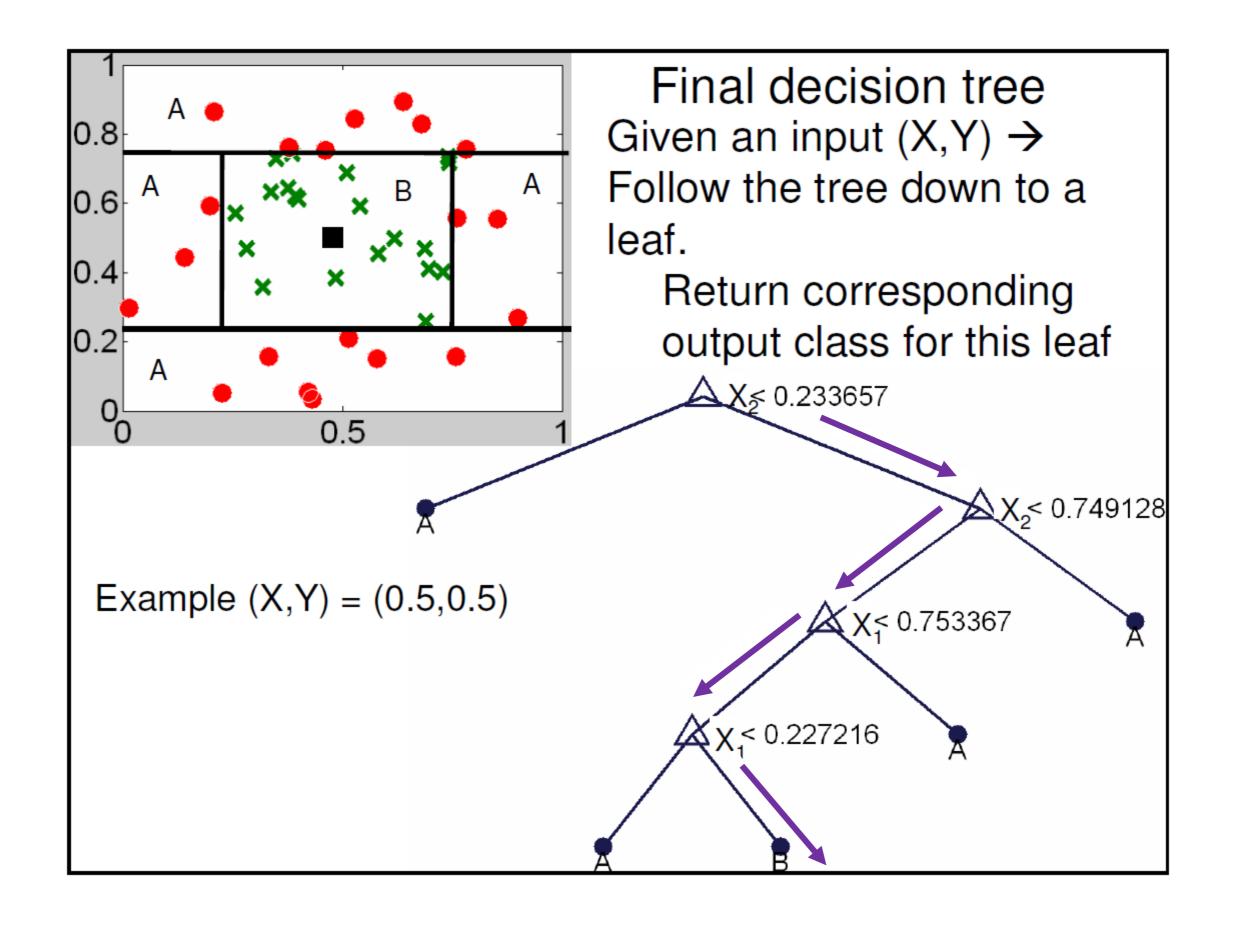

### **Basic Questions**

 How to choose the attribute/value to split on at each level of the tree?

 If the tree is too large, how can it be pruned?

## When to stop splitting? Common strategies:

- 1. Pure and impure leave nodes
  - All points belong to the same class; OR
  - All points from one class completely overlap with points from another class (i.e., same attributes)
    - Output majority class as this leaf's label
- 2. Node contains points fewer than some threshold

4. Further splits provide no improvement in training loss ( $loss(T) \le loss(T_L) + loss(T_R)$ )

#### Decision Tree Algorithm (Continuous Attributes)

- LearnTree(X, Y)
  - Input:
    - Set X of R training vectors, each containing the values (x<sub>1</sub>,...,x<sub>M</sub>) of M attributes (X<sub>1</sub>,...,X<sub>M</sub>)
    - A vector Y of R elements, where  $y_i$  = class of the j<sup>th</sup> datapoint
  - If all the datapoints in X have the same class value y
    - Return a leaf node that predicts y as output
  - If all the datapoints in X have the same attribute value  $(x_1,...,x_M)$ 
    - Return a leaf node that predicts the majority of the class values in Y
      as output
  - Try all the possible attributes  $X_j$  and threshold t and choose the one,  $j^*$ , for which  $IG(Y|X_j,t)$  is maximum
  - X<sub>L</sub>, Y<sub>L</sub>= set of datapoints for which x<sub>j\*</sub> < t and corresponding classes
  - $-X_H$ ,  $Y_H$  = set of datapoints for which  $x_{j^*} >= t$  and corresponding classes
  - Left Child  $\leftarrow$  LearnTree $(X_L, Y_L)$
  - Right Child ← LearnTree(X<sub>H</sub>, Y<sub>H</sub>)

#### Decision Tree Algorithm (Discrete Attributes)

- LearnTree(X, Y)
  - Input:
    - Set X of R training vectors, each containing the values  $(x_1,...,x_M)$  of M attributes  $(X_1,...,X_M)$
    - A vector Y of R elements, where  $y_i = \text{class of the } j^{\text{th}}$  datapoint
  - If all the datapoints in X have the same class value y
    - Return a leaf node that predicts y as output
  - If all the datapoints in X have the same attribute value  $(x_1,...,x_M)$ 
    - Return a leaf node that predicts the majority of the class values in Y as output
  - Try all the possible attributes  $X_j$  and choose the one,  $j^*$ , for which  $IG(Y|X_j)$  is maximum
  - For every possible value v of  $X_{i^*}$ :
    - $X_v$ ,  $Y_v$ = set of datapoints for which  $x_{j^*}$  = v and corresponding classes
    - Child<sub>v</sub>  $\leftarrow$  LearnTree( $X_v, Y_v$ )

## Decision Trees So Far

- Given N observations from training data, each with D attributes X and a class attribute Y, construct a sequence of tests (decision tree) to predict the class attribute Y from the attributes X
- Basic strategy for defining the tests ("when to split") → maximize the information gain on the training data set at each node of the tree
- Problems (next):
  - Computational issues > How expensive is it to compute the IG
  - The tree will end up being much too big → pruning
  - Evaluating the tree on training data is dangerous 
     overfitting

## **Basic Questions**

- How to choose the attribute/value to split on at each level of the tree?
- When to stop splitting? When should a node be declared a leaf?
- If a leaf node is impure, how should the class label be assigned?

 If the tree is too large, how can it be pruned?

# What will happen if a tree is too large?

Overfitting

High variance

Instability in predicting test data

# How to avoid overfitting?

Acquire more training data

Remove irrelevant attributes (manual process – not always possible)

Grow full tree, then post-prune

Ensemble learning

## Reduced-Error Pruning

Split data into training and validation sets

Grow tree based on training set

#### Do until further pruning is harmful:

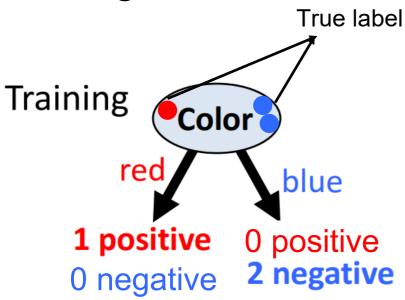

- 1. Evaluate impact on validation set of pruning each possible node (plus those below it)
- 2. Greedily remove the node that most improves validation set accuracy

## How to decide to remove it a node using pruning

 Pruning of the decision tree is done by replacing a whole subtree by a leaf node.

 The replacement takes place if a decision rule establishes that the expected error rate in the subtree is greater than in the

single leaf.

3 training data points
Actual Label: 1 positive and 2 negative
Predicted Label: 1 positive and 2 negative

3 correct and 0 incorrect

6 validation data points
Actual label: 2 positive and 4 negative
Predicted Label: 4 positive and 2 negative
2 correct and 4 incorrect
